Towards Component-Based Development of Textual Domain-Specific Languages

Andreas Wortmann
Software Engineering, RWTH Aachen University, http://www.se-rwth.de/

Abstract—Software-intensive systems are developed with experts of different domains. This requires relying on their domain expertise in software, which raises the need for domain-specific languages (DSLs) to bridge the gap between the problem space of the experts’ experience and software development. Developing suitable DSLs still is prohibitively complex due to the lack of pervasive concepts for DSL reuse. Existing concepts either give rise to a conceptual gap between their abstractions and language definition constituents or are tied to specific technological spaces. To mitigate this, we present a novel conceptual model for the systematic reuse of textual DSLs. This technology-independent model promotes modularity and reusability based on language families that exhibit specific reuse interfaces. To realize these concepts, we conceived an extensible modelling infrastructure that supports engineering reusable textual DSLs using the MontiCore language workbench. This enables systematic reuse of textual DSLs for compatible technological spaces from which DSL engineers in many domains can greatly benefit.

I. MOTIVATION

Society increasingly depends on systems developed by experts of various domains using domain-specific languages (DSLs) [1]. DSLs have become innovation drivers in many disciplines, including automotive, avionics, civil engineering, Industry 4.0, robotics, and software engineering itself. This, e.g., led to the engineering of over 120 DSLs for software architectures [2] used in different domains and various technological spaces [3]. All of these need to be developed, maintained, and evolved on their own, which is costly, error-prone, and hinders progress in the multi-domain engineering of modern software-intensive systems.

Research in software language engineering (SLE) [4] investigates the efficient and reliable engineering, maintenance, deployment, use, and evolution of DSLs to support software engineers and domain experts in efficiently developing future systems. Despite attempts to a systematic SLE, many DSLs are engineered ad-hoc, for very specific challenges, and very limited purposes only [5]. Hence, research has produced a multitude of solutions to facilitate creating DSLs. These include on metamodels [6], grammars [7], or abstract data types [8], interpreters [9] or code generators [10], and well-formedness rules defined in metalanguages [8] or programming languages [11]. For these, the SLE community has proposed various reuse techniques, based on experiences from general software reuse (e.g., polymorphic [12] and parametric [13] reuse, composition [7] or variability [14]). Although these techniques address a wide range of scenarios, most support specific parts of DSL definitions (e.g., abstract syntax or code generators) only and are limited to specific technological spaces. This complicates the engineering and customization of real-world DSLs for different usage scenarios, which ultimately hinders systems engineering with domain experts.

To mitigate this, we present the COLD4TXT conceptual model for component-based language development of textual DSLs that realize behavior with code generators (txtDSLs). In this model, language components with explicit interfaces of required and provided grammar rules, well-formedness rules, and code generators are the principal elements of reuse. Feature models arrange these components following their required and provided extension points to language families. Thus selecting features governs how the language components are composed. Based on this model, we present a systematic method to describe and resolve the component’s variability as well as their customization.

As the technical realizations of composing grammars, well-formedness rules, and code generators have been presented already [10], [15], this contribution illustrates their conceptual framework consisting of:

1) The COLD4TXT conceptual model for reusable txtDSL components featuring explicit interfaces of required and provided elements.
2) A systematic method for engineering languages based on reusable txtDSL components.
3) A realization of both with the MontiCore language engineering workbench.

With these, reusing language components in different language families can greatly facilitate engineering DSLs.

In the following, Sec. II motivates our method by example. Afterwards, Sec. III presents txtDSL language components and Sec. IV our method to reuse theses for efficient txtDSL engineering. Ultimately, Sec. V debates observations, Sec. VI discusses related work, and Sec. VII concludes.

II. EXAMPLE

Consider using architecture description languages (ADLs) [2] – DSLs for the specification of software architectures – for the different departments of a large corporation. In each of these departments, some developers occasionally, maybe once a week, (re-)model parts of a specific software architecture (e.g., of a train, a factory, or a mobile service robot). Instead of learning overly generic ADLs and operating with complex modeling guidelines that describe how to properly model with these, modelers of each department should be able to use their specific terminology
and learn only the modeling elements required for their specific application.

Hence, while in general, these ADLs require some notion of components, ports, and connectors, each department has domain-specific requirements for the ADLs to be used:

- Department A (trains) requires components that support dynamic reconfiguration via components modes [16] to enable switching components related to country-specific technology when the train crosses a border.
- Department B (smart factories) demands components with assumption/guarantee contracts [17] that facilitate correct integration of new components when the factory reconfigures.
- Department C (robotics) demands novel connectors that support bridging architecture models with the robot operating system (ROS) [18].

Developing a general ADLs that captures all of these concepts is not feasible as it complicates modeling in departments where only some of these modeling elements are not required. Alternatively developing three specific ADLs – each with their specific infrastructure (e.g., parsers, model checkers, code generators) – independently is costly and inefficient.

Instead, building suitable language components and combining these as required can significantly reduce the effort of fulfilling the departments’ requirements. For our example, consider the language family of Fig. 1: this family contains the language features required by the different departments and each feature is realized by a language component comprising a combination of grammar, well-formedness rules, and code generators. By developing independent language components that realize the different features and by leveraging variability modeling techniques, the configuration of the base ADL for the different departments only requires selecting the appropriate language components and (semi-)automatically integrating these. If no appropriate features are available, developing and integrating novel language components and integrating these into existing language families reduces the effort of building a suitable ADL.

Our method to engineer and reuse language components considers both, planned variability and opportunistic reuse, and supports semi-automated composition of language component constituents in the technological space of the MontiCore [11] language workbench.

III. COLD4TXT LANGUAGE COMPONENTS

The conceptual model of COLD is a vision of language reuse that requires concretization. For txtDSLs, we have developed the COLD4TXT variant of COLD which realizes variability, explains how resolving variability affects the language components, how variability and customizability interact, how variability, customizability, the language facets’ artifacts relate, and provides modeling techniques to realize this. At its core, COLD4TXT resolves variability and customizability through the additive composition of language components according to their explicitly provided and required extension points.

To enable this, COLD4TXT differs from COLD: In COLD4TXT, language families and language components replace language concerns and language facets of COLD, respectively: The language concerns of COLD provide both variability and customizability. This entails that they provide the complete customizability of their intrinsic language product line and express this towards the user despite only a small subset of customization options being available in the language product derived from the product line (namely these provided by the features selected for the product). In contrast, customizability should express means for tailoring languages that are not resolved by variability. Therefore, the language component comprising the derived language product provides customizability options instead. Moreover, to enable the proper composition of language components based on a feature selection, the COLD4TXT language components yield interfaces themselves. These interfaces guide and restrict their use in the variation interface’s feature model and enable composing two language components (semi-)automatically, with only the implementation of adapters for generator composition requiring manual interaction [10]. To explain the effects of resolving variability and customizability in COLD4TXT, a language component consists of a

- one language component interface,
- one customization interface,
- up to one grammar artifact,
- arbitrary many well-formedness rule artifacts, and
- arbitrary many code generator artifacts.

The language component interfaces explicitly provide or require language grammar productions, well-formedness rules, or code generators. Also, they may yield constraints between these (e.g., representing whether an extension point is optional or mandatory, or to express that selecting a provided code generator entails selecting a grammar production as well). The provided extension points for grammar rules identify productions of the contained CFG that are meant for reuse (e.g., expressions of an imperative modeling language, method
signatures of a class diagram language, . . . ). The required extension points for grammar productions explicite productions that demand (optional or mandatory) extension for the contained syntax to be completed.

Specifying required well-formedness rules within the interface either demands for giving complete specifications of the required well-formedness rules behavior (i.e., their implementation) or specifying conditions under which an independently provided well-formedness rule is suitable for the required rule (i.e., some form of acceptance tests). The former entails having a specification that is precise enough to become a implementation automatically and the latter testing rarely would be complete. Hence, we decided to consider the set of well-formedness rules of a language component as its extension point. Thus, a language component can provide arbitrary many well-formedness rules that may or may not be used by other components, but it cannot (yet) describe that it requires additional well-formedness rules. This is subject to ongoing work. For code generators, language components leverage the notions of producer interface and product interface as introduced in [10]. Hence, language components may provide and require extension points that declare exactly one producer interface and one product interface. The customization interfaces of language interfaces comprise parameters of well-formedness rules and generators that are not meant to be resolved through the closed variation of language families but enable open customization instead. Such customization could be the numbers of initial states supported in models of a language component for an automaton DSL or the path a generator should produce artifacts in.

The language interfaces ground their required and provided extension points the artifacts of their language components. Here, the red concepts (solid lines) represent the language components and the yellow concepts (dashed lines) highlight their customization interface parts. The language components are part of language families as depicted in Fig. 2: aside from at least one language component, a language family contains a variation interface comprising a specific child feature implements the extension points of its parent feature and specifies constraints between features in the Feature2ComponentMapping.

The language components are composed based on the arrangement of language components in the variation interfaces’ feature model. From this, a new language component comprising their (possibly composed) artifacts together with a derived interface are synthesized. If there are required extension points not fulfilled by the selected features, these become part of the new component’s interface.

COLD4TXT is realized in a language engineering framework using the MontiCore language workbench. To this end, we have developed modeling languages for language families, language components, feature configurations, and customization configurations as well as a toolchain that supports resolving variability and customizability.
Fig. 5. Model of the Expression component sketched in Fig. 1.

The language family CorpADL of our example (cf. Fig. 1) can be represented as illustrated in Fig. 3. This family describes which language components it comprises (ll. 2-3), its variation interface in terms of a feature model (ll. 4-10), and defines its features (ll. 11-24). A feature either is a root feature (at most one), an abstract feature solely for grouping other features (such as the feature Component), or is realized by a language component. Each feature of the latter kind defines how the provided extension points of its language component are mapped to the required extension points of its parent feature. For instance, selecting the feature Invariants entails that (1) its production Expression will be embedded [15] into the extension point Expr of the language component AsmGarContracts (l. 21); (2) its well-formedness rules provided via the extension point All will be reused (l. 22); and (3) its code generator provided via the extension point Expressions2POJO will be embedded into the code generator Guard2Java of language component AsmGarContracts (l. 23). The well-formedness rules of the language family ensure that these mappings are valid w.r.t. the language components illustrated in Fig. 4 and Fig. 5.

The next section explains how these language components are combined.

IV. DERIVING LANGUAGES

Modeling language families with COLD4TXT first demands its instantiation for a specific technological space by providing modules for (1) analyzing the compatibility of COLD4TXT models with the referenced technology space artifacts and (2) composing these artifacts according to COLD4TXT specifications as depicted in Fig. 6. The former modules, for instance, check whether a well-formedness rule provided by a language component exists or whether a grammar production declared as an extension point indeed is an interface production. The latter modules take composition instructions (the binding mappings) and related artifacts, and compose these accordingly. For MontiCore, these modules are provided. Language engineers than can use this instance of COLD4TXT to engineer language components. Language family developers then can reuse these in different contexts through arranging these in the variation interfaces. Language family users then select the desired language features matching their requirements and use the COLD4TXT instance to synthesize a suitable language component. If this language component is incomplete w.r.t. its mandatory required extension points or parameters, it cannot be used as a DSL yet. Then, the language family user has to specify the missing customization configuration, before a fully configured language component and the artifacts for a DSL in the corresponding technological space are derived.

For MontiCore, these artifacts are a synthesized CFG the union of the selected well-formedness rules, and a code generator composed along its producer and product interfaces. These artifacts can be processed by MontiCore to produce a DSL that is completely independent of language families and language components. Moreover, the (possibly incomplete) language components derived from resolving variability and customizability can be used as parts of other language families again, which facilitates their reuse.

Based on a feature configuration, the COLD4TXT framework composes the language components associated with the selected features pairwise and top-down. The resulting component yields the provided extension points of the parent and child components. For each mandatorily required extension point (e.g. Expr of language component ContractAutomata), if an implementation is defined by the binding mappings in the variation interface’s feature model, then this extension point becomes optional and is copied to the interface of the new component as well. The sets of well-formedness rules from the parent component and the ones from the selected provided extension point of the child component are merged and provided as a new extension point in the new component. For the CFGs, COLD4TXT expects the responsible modules of the specific technology space to produce combined CFGs and adapters between the participating code generators accordingly.

For instance, selecting the features “Asm/Gar Contracts” and “Invariants” depicted in Fig. 1 with the variation interface specified in Fig. 3 entails combining the language components ContractAutomata (Fig. 4) and Expressions (Fig. 5) accordingly. The resulting language component is given in Fig. 7. This component uses a synthesized CFG featuring contract automata and expressions (l. 2), the union of selected well-formedness rules, and the composed code generators. Its interface reduces the cardinality of the required grammar extension point Expr to optional (l. 7), adds the provided extension point Expression (l. 8) as well as the code generator for expressions (ll. 14-17) from the Expressions language component of Fig. 5, and provides a new set of well-formedness rules (ll. 19-23). As this component does not require further extension, specifying values for its parameters enables MontiCore to derive a complete DSL from it.

V. DISCUSSION

In contrast to the purely conceptual models of DSL reuse [19], [20], COLD4TXT on capturing all DSL definition constituents at a sufficient level of abstraction to support the precise explanation of the effects of composing these, binding their variability, and resolving their customizability on its own. The conceptual model of COLD4TXT aims to be independent of technological spaces as long as these enable to (1) identify grammar extension points; (2) compose grammars, sets of well-formedness rules, and code generators without
VI. RELATED WORK

Research on Language product lines (LPLs) [15], [22], [23] is scattered across different kinds of DSL definition constituents and technological spaces. While we developed a notion of LPLs for the technological space of MontiCore [15] in particular, there currently is no actionable understanding of the variability of complete txtDSLs (i.e., encompassing all four kinds of constituents). Moreover, (closed) variation rarely is connected with (open) customization to systematically reuse DSLs in general. There are only a few solutions that consider either txtDSL variation or customization across different kinds of DSL definition constituents. These include a few language workbenches [24], such as Argyle [23], Neverlang [7], or the combination of SDF and FeatureHouse [22].

In Argyle [23], DSLs are constructed from language assets that resemble concerns and comprise syntax, data types, and code generation templates. A feature model arranges assets according to their dependencies, which demands their white-box apriori composition that hinders the reuse of facets. In contrast, COLD4TXT will be based on our exploratory work [15] that makes extension points of concerns explicit and supports the black box composition of their artifacts through the generation of suitable adapters between these.

SDF and FeatureHouse realize variability based on compositional language modules containing grammar rules, typing rules, and evaluation rules [22]. It also focuses on the white-box composition of artifacts and interpretation. Similar partial solutions towards variation or customization of selected kinds of DSL definition constituents are available from a variety of language workbenches. For instance, ableC [25] is an extensible C language that leverages attribute grammars to reuse syntax and semantics, MPS [21] enables reuse of projectional languages with views and model transformations, and Spoofax [8] supports reuse of textual, interpreted languages. All of these focus on specific technological spaces.
VII. Conclusion

We have presented the novel COLD4TXT conceptual framework to facilitate reusing textual DSLs through systematic variability and customizability. In COLD4TXT, language families capture txtDSL variability as feature models and realize it via composition of language components according to their interfaces. Composing language components yields new language components that may demand further extension or customization before these can be translated into complete language components that may demand further extension or their interfaces. Composing language components yields new language components that may demand further extension or customization before these can be translated into complete language components. This facilitates engineering textual DSLs for different contexts and fosters the application DSLs.
